Outline

1. Essences of calculation the reactor antineutrino signal
   1.1 Creating antineutrinos in the nuclear reactors
   1.2 Propagation of the antineutrinos in the space
   1.3 Detection of the antineutrinos

2. Fission antineutrino spectrum
   2.1 The ‘ab initio’ summation method
   2.2 The electron spectrum conversion method
   2.3 Effects of forbidden decays to the fission antineutrino spectrum

3. Conclusions
Reactor anomaly problem: 6 % antineutrino missing.

Theoretical prediction including a new sterile neutrino, $|\Delta m^2| >> 1\,\text{eV}^2$, $\sin^2 (2\,\vartheta) = 0.12$

Experimental mean averaged $N_{\text{OBS}}/N_{\text{EXP}} = 0.943 \pm 0.023$

$\mu$ % Missing

Huber, Phys. Rev. C 84, 024617 (2011)
1. Essences of calculation the reactor antineutrino signal

1.1 Creating antineutrinos in nuclear reactors

In power reactors 99.9 % of the power comes from the fission of $^{235}\text{U}$, $^{238}\text{U}$, $^{239}\text{Pu}$ and $^{241}\text{Pu}$.
Antineutrinos are creating in the β-decays of neutron-rich fission products of $^{235}\text{U}$, $^{238}\text{U}$, $^{239}\text{Pu}$ and $^{241}\text{Pu}$:

$$\frac{A}{Z}X_N \rightarrow \frac{A}{Z+1}X_{N-1} + e^- + \bar{\nu}$$

$$S(E_\nu) = \sum_i f_i \frac{dN_i}{dE_\nu}$$

How to obtain the $f_i$?

$$f_i = \frac{P_{th} P_i}{Q_i}$$

The energy released in the fission of $i$-th actinide.

The power fraction of $i$-th actinide.

Many prescriptions for the antineutrino fission spectra of \( i \)-th actinide \( \frac{dN_i}{dE_{\bar{\nu}}} \) exist.

According to Mueller et al. the spectra of all four contributing isotopes are given in terms of the exponential of a polynomial of order 5:

\[
\frac{dN_i}{dE_{\bar{\nu}}} = \exp \left( \sum_i a_p^i E_{\bar{\nu}}^{p-i} \right)
\]

How is this formula correct? ...
1.2 Propagation of the antineutrinos in the space

1. The flux of antineutrinos decreases with the distance from the reactor $d$ as:

$$\Omega_d = \frac{\Omega_{\text{init}}}{4\pi d^2}$$

2. The electron antineutrinos oscillate and the survival probability can be written as:

$$P_{ee} = 1 - \sin^2 2\theta_{13} \left( \cos^2 \theta_{12} \sin^2 \Delta_{31} + \sin^2 \theta_{12} \sin^2 \Delta_{32} \right)$$

$$- \cos^4 \theta_{13} \sin^2 2\theta_{12} \sin^2 \Delta_{21},$$

$$\Delta_{ij} = \Delta m_{ij}^2 d / 4 E_{\nu}$$

1.3 Detection of the antineutrinos

Inverse beta decay (IBD)

\[ \bar{\nu}_e + p \rightarrow e^+ + n \]

The cross section of the IBD can be parametrized as

\[ \sigma_{IBD}(E_{\bar{\nu}}) = 10^{-43} cm^2 p_e E_e E_{\bar{\nu}}^{0.07056+0.02018\ln E_{\bar{\nu}}-0.001953\ln^3 E_{\bar{\nu}}} \]

The final formula for the antineutrino reactor signal

\[
N_{tot} = \varepsilon N_p \tau \sum_{i=1}^{N_{reactor}} \frac{P_{th}^i}{4\pi d_i^2} \langle LF_i \rangle \int dE_{\overline{\nu}} \sum_{k=1}^{A} \frac{p_k dN_{\overline{\nu}}}{Q_k dE_{\overline{\nu}}} P_{ee}(E_{\overline{\nu}}, d_i) \sigma_{IBD}(E_{\overline{\nu}})
\]

For the reference and comparison reasons the signal is calculated in Terrestrial Neutrino Units (TNU)
- Detector efficiency \( \varepsilon = 1 \)
- Number of free protons \( N_p = 10^{32} \) (= 1 kton of liquid scintilator detector)
- Time of measurement \( \tau = 3.15 \times 10^7 \) s (1 year)

**1 TNU**

= 1 detected neutrino by 1 kton liquid scintilator detector with effeciency \( \varepsilon = 1 \)

2. Fission antineutrino spectrum

2.1. The ‘ab initio’ summation method

In the ‘ab initio’ approach the aggregate fission antineutrino spectrum is determined by summing the contributions of all β-decay branches of all fission fragments

\[
\frac{dN_i}{dE_{\bar{\nu}}} = \sum_n Y_n(Z, A, t) \sum_{n,i} b_{n,i}(E_0^i) P_{\bar{\nu}}(E_{\bar{\nu}}, E_0^i, Z)
\]

- \(Y_n(Z, A, t)\) Number of beta decays of the fragment Z, A at given time t (fission yields)
- \(b_{n,i}(E_0^i)\) Branching ratios with endpoint energies \(E_0^i\) \(\sum_{n,i} b_{n,i}(E_0^i) = 1\)
- \(P_{\bar{\nu}}(E_{\bar{\nu}}, E_0^i, Z)\) Normalized anti-neutrino spectra shape for the i-th branch

\(n\) characterize ground and isomeric state
In applying the summation method several sources of uncertainty arise:

The fission yields $Y_n$ have been evaluated by several international database groups, but for many important fragments the yields involve large uncertainties.

The branching ratios $b_{n,i}$ are also not known for all fragments, and nor are the quantum numbers (spins and parity) of all of the initial and final states.

The shape of the $\beta$ decay spectrum $P_\nu(E_\nu, E^i_0, Z)$ is well known for allowed transitions. However $\sim 30\%$ of the transitions making up the aggregate spectra are known to be so-called first forbidden transitions and involve nuclear structure dependent combinations of several more complicated operators.
Need to sum beta spectra of around 800 fission products

The AB INITIO method describes the spectra with only 10-20% of accuracy

But it is applied for the $^{238}$U isotope.
2.2 The electron spectrum conversion method.

The second method of determining the $dN_i / dE_{\nu}$ spectra begins with the experimentally measured aggregate electron spectrum of each actinide i.

$$
\frac{dN_{ei}}{dE_e} = \sum_i a_i P_v^i (E_e, E_0^i, Z)
$$

The measured spectra are fitted by the sum of the 30-40 single beta spectra with the virtual endpoint energies $E_0^i$.

The antineutrino spectra one obtain with just replacing the electron energy by $E_0^i - E_{\nu}$

$$
\frac{dN_{\bar{\nu}i}}{dE_{\bar{\nu}}} = \sum_i a_i P_v^i (E_0^i - E_{\nu}, E_0^i, Z)
$$

The electron spectrum for thermal neutron fission of $^{235}\text{U}$, $^{239}\text{Pu}$ and $^{241}\text{Pu}$ were measured at ILL, Grenoble, France in 1980’s.

Beta–spectra, shape factors and finite-size corrections

\[ P_v^i(E_e, E_0^i, Z) = N \ p_e E_e (E_0 - E_e)^2 F_0(E_e, Z, A) \ C(E_e)(1 + \delta(E_e, Z, A)) \]

Normalization coefficient

Fermi function

Shape factors, for the allowed transition \( C(E_e)=1 \)

Finite – size, radiative, and weak-magnetism corrections

30% of the neutrino flux arises from the first forbidden beta transitions.
1. First ‘modern’ evaluations were done in late 1970 and early 1980
   \cite{Davis79,Vogel81,Klapdor82}

2. During the 1980-1990 a series of measurements of the electron spectra
   associated with the fission of $^{235}\text{U}$, $^{239}\text{Pu}$ and $^{241}\text{Pu}$ were performed at ILL
   Grenoble by Schreckenbach et al. These were converted into the electron
   antineutrino spectra by the authors.

3. New evaluation \cite{Mueller11} uses a combination of the ab initio
   approach with updated experimental data and the input from the
   converted electron. This results in the upward shift by $\sim3\%$ of the reactor
   flux.

   Huber 2011 obtain also the $\sim3\%$ shift using the electron conversion
   method with corrections

Inspired by slide of P. Vogel

All forbidden transitions are calculated as the unique forbidden — this can affect results a lot!

Fitted by 5 virtual beta allowed transitions with $Z=46$!
The obtained electron spectra do not correspond to the ILL experimental one within the experimental error!!!

The electron spectrum conversion method is used but adding more precise finite – size, radiative, and weak-magnetism corrections

\[ P_v^i(E_e, E_0^i, Z) = N \ p_e E_e (E_0 - E_e)^2 \ F_0(E_e, Z, A) \ C(E_e)(1 + \delta(E_e, Z, A)) \]

But no forbidden transitions included!
A.C. Hayes, PRL 112 (2014)

“Given the present lack of detailed knowledge of the structure of the forbidden transitions, it is not possible to convert the measured aggregate fission beta spectra to antineutrino spectra to the accuracy needed to infer an anomaly.”

“we estimate that the uncertainty in antineutrino spectra derived by the conversion method are about 5%. The uncertainties in the summation method are considerably worse and at least in the upper part of the antineutrino spectrum are probably up to the 20% level. We emphasize that these are our subjective estimates. They are based on educated guesses and they do not represent statistical variances.”

\]

The problem is that many authors use for their analysis plane wave shape factors which have incorrect form!
The difference is mainly obvious in the $GT_1$ matrix element.
We saw that spectra for the first forbidden unique beta decay differs from the allowed one, but the spectra associated with the other non-unique first forbidden nuclear matrix elements are quite similar to the allowed ones.

In fact, most of the non-unique first forbidden spectra are similar with the allowed ones.

Vladimir Tretiak [1] analyzed 38 measured first forbidden spectra [2] and compared it with allowed ones:

Among them
20 nuclei are allowed or very close to allowed

8 nuclei have deviation from the allowed shape in the region (5%, 10%)
10 nuclei have deviation more than 10 %
Especially $^{72}$Ga, $^{115m}$Cd, $^{170}$Tm have deviation (20%, 30%) and $^{210}$Bi (Rae) has deviation even more than 30%.

Why the spectrum is so different from the allowed one? Because of the cancelation effect between different nuclear matrix elements.
Since the shape of the non-unique first forbidden spectra depends strongly on the values of the nuclear matrix elements it is questionable if the analyzation of the neutrino spectra based on the spectra associated with the specific matrix element has a meaning.

Since we do not know the shape of the first non-unique first forbidden spectra and since many of them has allowed shape we threat the forbidden beta decays as a first unique beta decays and look at the deviations in the neutrino spectra.
A comparison between our results and Schreckenbach results $N_{v\text{ILL}}$

All beta decays are assumed to be 1. unique forbidden

30% are 1. unique forbidden, other allowed

Grey area - error stated in Schreckenbach

1.6%
1.1%
2.7%
1.71%
6.35%

Conclusions

The effects of the forbidden transitions to the fission antineutrino spectra were not be done correctly, till now. Even if they were some attempts i.e. A.C. Hayes, PRL 112 (2014).

At least we suggest that the proper shape factors, presented in our work should be used for the analysis.

From our simplified analysis it seems that including forbidden transitions has tendency to the increase the predicted number of neutrinos.

It also seems that shape factors has a subdominant role than the FS and WM corrections.

It is clear that including proper shape factor, FS, WM and radiative corrections is essential for the AB INITIO calculation, but have all these corrections sense in the case of the electron conversion method, where only virtual (not real!) beta branches are assumed? Maybe old Schreckenbach results are closer to the reality than the modern approaches...
